## Abstract

This project aims to compare and contrast the some commonly used sorting algorithms. The different sorting algorithms that will be tested will be tested on value range, and value size, in order to determine the best and worst case scenarios for each algorithm.

# 1 Introduction

## 1.1 Terms

This is a set of standard terms and variables that will be referenced to for explanations of the sorting algorithms, and their methods.

$n$  : The number of values that will be sorted by the sorting algorithms.

$r$  : The range for  $n$  that will be sorted.

*Values* : The stored values to be sorted, of  $n$  length, and in  $r$  range.

$t$  : The time in seconds that an algorithm takes to sort  $n$  values.

(*i*) Reference to specific line in referenced code example.

## 2 Algorithms

Here is a description of the algorithms that were a part of this research. In this section each algorithm will be described, and the method of its sorting will be explained in words, as well as with persudo code.

## 2.1 Bubble Sort

Bubble sort works off of a method where the algorithm only focus on a two terms of the list at a time. Bubble sort compares two adjacent pairs of numbers, and switches them to be in the correct order. The algorithm moves through the list until it reaches the end. However, this does not mean that the list is sorted, so the algorithm returns to the beginning and repeats the loop switching items when necessary until there are no more items that need to be switched.

This method can then be optimized through several methods. One optimization method that is implemented

in this example is setting a limit to the maximum on the loop. If there are no more values that need to be swapped, then the algorithm does not need to continue to check those values. So simply the algorithm can track a limit to the maximum value that needs to be checked, and instead of looping through the entire list of values, the algorithm can loop through a select number of the values from the lists.

Here is an example of the pseudo code, followed by a line by line explanation of the code. A example of bubble sort in actual code can be found in A.1.

```
function BUBBLESORT(Values)
  n =length(Values)
  while n  $\neq$  0 do
    newn = 0
    for i = 1 to n - 1 do
      if Values[i - 1] > Values[i] then
        Swap(Values[i - 1], Values[i])
        newn = i
      end if
    end for
    n = newn
  end while
end function
```

(1) The definition of the function with an input of *Values* which is a list of values to be sorted.

(2) The beginning of a loop the follow until *Values* is completely sorted.

(3) The definition of *newn* variable which will be used to determine the maximum limit on the sorting loop.

(4) The for loop that begins at the first two items in *Values* and ends at

the *n* - 1 item in *Values*.

(5) The if check to determine if the two items need to be switched.

(6) Swaps the two compared items positions.

(7) Sets *newn* to *i* in order to move the upper limit up to the current maximum necessary swap position.

(10) Sets *n* to *newn* essentially setting the upper limit on the for loop.

Bubble sort is considered a very poor method for sorting algorithms, and is most often less efficient than other extremely simple sorting algorithms. Bubble sort has a complexity of  $O(n^2)$ . This complexity means that for an increase in the  $n$ , the com-

plexity of the algorithm, and the time requirement grow exponentially. For small  $n$  values this algorithm would work sufficiently, but as the number of values grows this algorithm becomes much less efficient, and soon becomes useless.

## 2.2 Bucket Sort

Bucket sort works with a method of dividing the set of values into smaller and smaller sub groups. The algorithm creates a set of "buckets" that it then sorts the values into. This method can be simplified as sorting groups at a time. For example any values that are in the first 10% will be placed in the first bucket, then values in the second 10% will be placed in the second bucket. This continues until all values have been placed into a bucket. Then the algorithm is run again with each of the bucket that were just created as the main bucket. Each of the terms that was placed in the first bucket are then again sorted into ten more buckets. This is done until all values are in their own bucket. Then the buckets are placed back together in order. This results in the sorted list of values.

Bucket sort can as well be optimized. Bucket sort is very effective

at breaking up the large data set into smaller semi-sorted sets of data, but at a point bucket sort becomes inefficient. Because going through algorithm until every value has its own bucket requires much more calculations than some optimized algorithms. One such optimization is to use bucket sort, then once the number of elements in a bucket is below a specified level, then that bucket is sorted using some other sorting algorithm. Or another option is to place all the buckets back into a single semi-sorted list, and then use *Insertion Sort* to complete the sorting, because *Insertion Sort*'s runtime is based off of an elements distance from its final position.

Here is bucket code in persudo code, accompanied with a line by line explication. Real examples of code can be found in A.2.

```

function BUCKETSORT(Values, n)
  Arrays <- new array of n empty lists
  for i = 0 to (length(Values)-1) do
    insert Values[i] into Arrays[floor(Values[i]/(rangeof(Values)/n))]
  end for
  clear Values
  for i = 0 to n - 1 do
    append BUCKETSORT(Arrays[i], n) to Values
  end for
  return Values
end function

```

(1) The definition of the function with an input of *Values* which is a list of values to be sorted, and  $n$  which is the number of buckets to sort into.

(2) Creates a new list of  $n$  empty list or "buckets".

(3) Beginning of a for loop that goes through the length of *Values* and sorts them into the *Arrays*.

(4) The method used for determining what *Array* to place the item into is done by dividing the value of the item by the value range of the array, then rounding down. This will result in returning the correct *Array* for the item to be sorted into.

(6) Clears *Values* of any items to

prepare it for rewriting with sorted results.

(7) Beginning of a for loop that goes through every list in *Arrays*

(8) Recursively calls bucket sort with each new list of items that was placed in each bucket. Eventually there will only be a single item in a bucket and it cannot be sorted. The returned results will be appended together into a complete and sorted list of values.

(10) This sorted list of values is then returned for any functions higher up in the chain of being called in the recursive function.

Bucket sort is a moderately effective sorting algorithm, but could be greatly improved with some simple optimizations. On its own Bucket sort has a complexity of  $O(n)$ , as there is a need for a bucket for every element

that is being sorted. This means that it is fairly efficient, but still could be greatly improved by the implementation of a limit for the minimum size of bucket before initiation a different sorting algorithm.

## 2.3 Counting Sort

Counting Sort uses a method
